

Test 01

Q1) What is perfect secrecy? Describe a system that achieves it.

Ans • Perfect secrecy (or information-theoretic -0.5 marks. secure) means that the ciphertext conveys no information about the content of the plaintext.

• In effect this means that, no matter how much ciphertext you have, it does not convey anything about what the plaintext and key were.

• Formally, a system has perfect secrecy if the probability of any plaintext message remains the same even after observing the ciphertext.

$$P(M|C) = P(m) \quad \text{for all msg } m \text{ and ciphertext } C.$$

- This means that knowing the ciphertext does not help an attacker to guess the plaintext, even with unlimited computational power.

* System achieving Perfect Secrecy:- One-Time Pad (OTP)

The one-time pad is the only known encryption that achieves perfect secrecy.

• Description :-

a) Each plaintext is combined with a truly random key of the same length as the plaintext.

b) Encryption is usually done using XOR (or modular addition)

c) Each key is used only once and then discarded

• Why OTP achieves perfect secrecy :-

a) Every possible plaintext is equally likely for a given ciphertext.

b) without the key, the ciphertext provides no statistical info about the msg.

(i) even an attacker with infinite computational power cannot break it.

• Conditions required for perfect secrecy in OTP

1. The key must be truly random
2. The length must be equal to msg length
3. Key must be used only once
4. Key must be kept completely secret.

• Limitations :-

Although OTP is theoretically secure, it is impractical in real systems due to difficulties in secure key generation, storage and distribution.

Ques 2) Explain briefly the concept : One-way function, one-way hash function, trapdoor one-way fn.

One way functions:- It is, by definition, a mathematical function that is easy to compute in forward direction but computationally infeasible to invert.

Forward computation : $y = f(x)$ is easy

Inversion : $x = f^{-1}(y)$ is infeasible.

• One-way fns are the foundation of modern asymmetric (or public key) cryptography. In fact, all cryptographic algo used to protect data and communicate base their security on the difficulty of inverting these objects.

Eg:- ① Diffie-Hellman key exchange $\Rightarrow f(x) = g^x \text{ mod } p$.
+ calculating power n -th of g modulo p is easy
but given a true integer n less than p , finding element x for which $g^x = h \text{ mod } p$ is hard.

② Multiplying 2 large primes is easy but factoring is hard.

One way hash function:- one way hash function maps data of arbitrary length to a fixed-length hash value and is infeasible to reverse.

furthermore, a one-way hash function is designed in such a way that is hard to reverse the process, that is, to find a string that hashes to a given value (hence the name one-way).

A document's hash can serve as a cryptographic equivalent of the document since it is infeasible to produce a document that would hash to a given value or find two documents that hash to same value.

This makes a one-way hash function a central notion in public key cryptography. When producing a digital signature for a document, we no longer need to encrypt the entire document with a sender's private key (which can be extremely slow). It is sufficient to encrypt the document's hash value instead.

- Properties:-
 - ① Pre-image resistance :- given h , it is hard to find x such that $H(x) = h$
 - ② Second preimage resistance :- hard to find another $x' \neq x$ with same hash.
 - ③ Collision resistance :- hard to find any two different inputs with the same hash.

Trapdoor one-way function:- A trapdoor one-way function is a special type of one-way function that is easy to invert only if a secret trapdoor is known.

- without trapdoor :- Inversion is infeasible
- with trapdoor :- Inversion becomes easy.

These have particularity of being easy to reverse as long as some secret information is known (trapdoor), while, otherwise, they act like a normal one-way fn.

Eg:- RSA is a trapdoor one-way fn because computing $f(m) = m^e \text{ mod } N$ is easy but reversing it is hard unless the private key d is known which acts as a trapdoor.

Why is it hard to reverse?

$$\text{Given } c = m^e \text{ mod } N$$

Finding m from c means:

- Taking an e -th root modulo N
- This is extremely hard without knowing p, q .

Perfect Secrecy and OTP

DEPARTMENT OF COMPUTER SCIENCE AND ENGINEERING

NITK-SURATHKAL

II Sem M.Tech (CSE-IS) Sub: Network Security Surprise Test :01

Date: 30-1-2025 Max Marks: 25

Note : Answer all the questions. Missing data may be suitably assumed.

1. What is Perfect Secrecy? Describe a system that achieves it. -05 Marks
2. Explain briefly the concepts: one-way function, one-way hash function, trapdoor one-way function. -05 Marks
3. Describe the three main concerns with the use of passwords for authentication. Explain what is meant by a social engineering attack on a password. -05 Marks
4. Explain how access control lists are used to represent access control matrices. Describe the environments in which they are widely used and their advantages and disadvantages. -05 Marks
5. An ideal password authentication scheme has to withstand a number of attacks. Describe five of these attacks. -05 Marks

Give me answer to question 1

Perfect Secrecy

A cryptosystem is said to have **perfect secrecy** if the ciphertext gives **no information at all** about the plaintext.

Formally, a system has perfect secrecy if the probability of any plaintext message remains the same even after observing the ciphertext:

$$P(M | C) = P(M) \quad \text{for all messages } M \text{ and ciphertexts } C$$

This means that knowing the ciphertext does **not** help an attacker guess the plaintext, even with unlimited computational power.

System Achieving Perfect Secrecy: One-Time Pad (OTP)

The **One-Time Pad** is the only known encryption system that achieves perfect secrecy.

Description:

- The plaintext is combined with a **truly random key** of the **same length** as the plaintext.
- Encryption is usually done using XOR (or modular addition).
- Each key is used **only once** and then discarded.

Why OTP achieves perfect secrecy:

- Every possible plaintext is equally likely for a given ciphertext.
- Without the key, the ciphertext provides no statistical information about the message.
- Even an attacker with infinite computational power cannot break it.

Conditions required for perfect secrecy in OTP:

1. The key must be **truly random**.
2. The key length must be **equal to the message length**.
3. The key must be **used only once**.
4. The key must be kept **completely secret**.

Limitation:

Although OTP is theoretically secure, it is impractical in real systems due to difficulties in secure key generation, storage, and distribution.

Hence, **Perfect Secrecy is achievable in theory (via OTP), but difficult to deploy in practice.**

Answer question 2

One-Way Function, One-Way Hash Function, and Trapdoor One-Way Function

One-Way Function

A **one-way function** is a function that is **easy to compute** in the forward direction but **computationally infeasible to invert**.

- Forward computation:

$$y = f(x) \quad \text{is easy}$$

- Inversion:

$$x = f^{-1}(y) \quad \text{is infeasible}$$

Example: Multiplying two large prime numbers is easy, but factoring their product is hard.

One-Way Hash Function

A **one-way hash function** maps data of **arbitrary length** to a **fixed-length hash value** and is infeasible to reverse.

Properties:

1. **Preimage resistance** – given h , it is hard to find x such that $H(x) = h$.
2. **Second preimage resistance** – hard to find another $x' \neq x$ with the same hash.
3. **Collision resistance** – hard to find any two different inputs with the same hash.

Example: SHA-256 used for password storage and data integrity.

Trapdoor One-Way Function

A **trapdoor one-way function** is a special type of one-way function that is **easy to invert only if a secret trapdoor is known**.

- Without trapdoor: inversion is infeasible.
- With trapdoor: inversion becomes easy.

Example:

- **RSA algorithm**
 - Encryption: easy using the public key
 - Decryption: feasible only using the private key (trapdoor)

Summary

- **One-way function:** Hard to reverse for everyone.
- **One-way hash function:** One-way function producing fixed-length output for integrity and passwords.
- **Trapdoor one-way function:** Hard to invert unless secret information is available.

✓ These concepts are fundamental to modern cryptography and secure communication.

explain question 3

Question 3: Passwords for Authentication & Social Engineering Attacks

Three Main Concerns with Using Passwords

1. Weak or Guessable Passwords

- Users often choose **simple, short, or predictable passwords** (e.g., name, date of birth, "123456").
- Such passwords are vulnerable to **dictionary attacks** and **brute-force attacks**.

2. Password Reuse

- The same password is often reused across **multiple services**.
- If one website is compromised, attackers can use the leaked password to access **other accounts** (credential stuffing).

3. Password Theft

Passwords can be stolen using:

- **Keyloggers**
- **Phishing websites**
- **Shoulder surfing**
- **Malware**

Once stolen, the attacker can directly impersonate the user.

Social Engineering Attack on a Password

A **social engineering attack** is an attack where the adversary **tricks the user into revealing their password**, rather than breaking it technically.

How it Works:

- The attacker pretends to be a **trusted entity** (IT admin, bank, email provider).
- The victim is asked to **enter or share their password** due to:
 - Account verification
 - Security warning
 - Urgent request

Example:

- A fake email saying:
"Your account will be suspended. Click here and log in immediately."
 - The link leads to a **fake login page**.
 - The user enters credentials, which are captured by the attacker.
-

Summary

- Password systems suffer due to **human behavior**, not just technical flaws.
- Social engineering bypasses cryptography by **exploiting trust and fear**.
- This makes password-based authentication inherently vulnerable.

 This is why modern systems use **multi-factor authentication (MFA)** to strengthen security.

answer question 4

Question 4: Access Control Lists (ACLs) and Access Control Matrices

Access Control Matrix

An **access control matrix** is a conceptual model that represents the permissions of subjects on objects.

- **Rows** → Subjects (users, processes)
- **Columns** → Objects (files, resources)
- **Entries** → Access rights (read, write, execute)

Example:

	File1	File2
User1	R,W	R
User2	R	—

Access Control List (ACL) Representation

An **Access Control List (ACL)** is a **column-wise representation** of the access control matrix.

- Each **object** has a list specifying:
 - Which **subjects** can access it
 - What **permissions** they have

Example (for File1):

```
mathematica

File1 ACL:
User1 → Read, Write
User2 → Read
```

Thus, ACLs store only **non-empty entries** of the access control matrix, making them efficient in practice.

Environments Where ACLs Are Widely Used

- **Operating Systems**
 - UNIX/Linux file permissions
 - Windows NTFS ACLs
- **Databases**
 - Table and view access permissions

- **Network Devices**
 - Routers and firewalls for packet filtering
 - **Cloud Systems**
 - Access to storage buckets and services
-

Advantages of ACLs

1. **Easy to manage per object**
 2. **Efficient storage** (only permitted entries stored)
 3. **Supports fine-grained permissions**
 4. **Widely implemented and well understood**
-

Disadvantages of ACLs

1. **Difficult to determine all accesses of a subject**
 2. **Poor scalability** in very large systems
 3. **Revocation of user access can be complex**
 4. **Not ideal for dynamic environments**
-

Summary

- ACLs are a **practical implementation** of the access control matrix.
- They are best suited for **object-centric security models**.
- Despite limitations, ACLs remain one of the most commonly used access control mechanisms.

 Hence, ACLs effectively translate theoretical access control matrices into real-world systems.

answer question 5

Question 5: Attacks an Ideal Password Authentication Scheme Must Withstand

An ideal password authentication system should be resistant to multiple types of attacks. **Five important attacks are described below:**

1. Brute Force Attack

- The attacker tries **all possible password combinations** until the correct one is found.

- **Defense:** Strong password policies, account lockout, rate limiting.
-

2. Dictionary Attack

- Uses a **predefined list of common passwords** and words instead of random guesses.
 - Very effective against weak or predictable passwords.
 - **Defense:** Enforce complex, uncommon passwords.
-

3. Replay Attack

- Attacker captures authentication data and **reuses it** to gain access.
 - **Defense:** Nonces, timestamps, challenge-response mechanisms.
-

4. Eavesdropping Attack

- Passwords are intercepted while being transmitted over the network.
 - Common in plaintext or weakly encrypted protocols.
 - **Defense:** Secure channels like SSL/TLS, encrypted authentication.
-

5. Phishing / Social Engineering Attack

- User is tricked into **revealing their password** through fake websites or emails.
 - **Defense:** User awareness, MFA, anti-phishing mechanisms.
-

Summary

An ideal password system must protect against:

- Guessing attacks (brute force, dictionary)
- Network-based attacks (eavesdropping, replay)
- Human-targeted attacks (phishing)

 This highlights why **strong passwords + secure protocols + multi-factor authentication** are necessary for robust authentication security.
